Abstract—We investigate cooperative effects of noise and periodic forcing in an optical bistable system. It has been demonstrated in recent experiments by Grohs et al. that noise-induced switching between low and high output intensity can be synchronized to the stochastic resonance often by a small periodic modulation of the input intensity. Here we present theoretical results for stochastic resonance in optical bistable systems.

1. MODEL AND BASIC EQUATIONS

A model for optical bistability was introduced by Bonifacio and Lugnér [1]. For the amplitude $y$ of the input light and the transmitted amplitude $x$, they have derived the equation of motion

$$ \dot{x} = y - x - \frac{2x}{1 + x^2} + \sqrt{D \frac{x}{1 + x^2}} \Gamma(t), $$

where $\Gamma$ represents uncorrelated, Gaussian distributed noise with zero mean. A weak periodic modulation of the input intensity is taken into account by adding a periodic term to $y$, i.e., $y = y_{\text{dc}} + A \cos(\Omega t + \Phi)$. For the probability density of the transmitted amplitude, $P(x, t)$, we find the Fokker–Planck equation

$$ \frac{\partial}{\partial t} P(x, t) = -\frac{\partial}{\partial x} \left[ y_{\text{dc}} x - \frac{2x}{1 + x^2} + D \frac{x}{1 + x^2} \right] P(x, t) + \frac{\partial^2}{\partial x^2} \frac{x^2}{1 + x^2} P(x, t). $$

The spectral density of the transmitted amplitude has $\delta$-spikes at multiples $n\Omega$ of the driving frequency $\Omega$, with the corresponding weight $w_n$ being a measure for the output power at the frequency $n\Omega$. They can be expressed in terms of the Fourier coefficients of the input periodic, asymptotic mean value $\langle x(t) \rangle$?

$$ \langle x(t) \rangle = \sum_{n=-\infty}^{\infty} |M_n| \exp[i(n\Omega t + \Phi_n)] $$

by

$$ w_n = 2\pi |M_n|^2. $$

2. AMPLIFICATION OF THE OPTICAL SIGNAL

The amplification of the periodic signal is given by the ratio of the transmitted power at the driving frequency and the input power [3]

$$\eta(\Omega) = 4 \frac{|M|^2}{A^2}. \quad (5)$$

We can solve the Fokker-Planck equation (2) numerically for the asymptotic mean value $$\langle x(t) \rangle_w$$ by using the method of matrix continued fractions [4]. In doing so we follow the reasoning put forward in refs [2 and 3] where the stochastic resonance in a symmetric double well has been investigated. The numerical results for $$\eta_d$$ are shown in Fig. 1 for various frequencies by the solid lines. Figure 1(a) corresponds to choosing $$\gamma_D$$ such that $$P_{ex}(t)$$ shows two peaks of nearly equal height in the limit $$D \to 0$$ what we call the ‘symmetric case’, and Fig. 1(b) corresponds to an ‘asymmetric case’, where the peaks of the stationary probability have different probabilistic weights in the limit $$D \to 0$$.

In the symmetric case we observe stochastic resonance [5] very much like in the quartic double well potential, i.e. a peak in the amplification of the modulation as a function of the noise intensity when the sum of the mean sojourn times in both stable states equals the period of the driving (these values of $$D$$ are indicated as vertical dashed lines in Fig. 1).

In the asymmetric case, the peak of the amplification is suppressed, because—in contrast to the symmetric case—the corresponding contribution (i.e. the weight $$g_T$$ in (5)) of hopping motion to the response of the system disappears exponentially for small noise [6]. The remaining maximum is only the tail of the amplification by synchronization at large noise.

The numerical results are compared in Fig. 1 with those obtained within linear response approximation $$\tilde{\eta}_I$$ (dotted lines). In this approximation we find in terms of the response function $$R(t)$$

$$\langle x(t) \rangle_w - \langle x \rangle_w = \int_{-\infty}^{\infty} R(t - t') A \cos(\Omega t' + \varphi) \, dt' - \int_0^t P_d(x) \, dx. \quad (6)$$

with the stationary solution $$P_d(x)$$ of the undriven system. The response function $$R(t)$$ is expressed via a fluctuation theorem by a correlation function $$K(t)$$ of the undriven system

$$R(t) = \frac{d}{dt} \langle x(t) h(x(0)) \rangle = \frac{d}{dt} K(t) \quad (7)$$

with $$h(x) = (1/D)(-x + 2x + 3x^2)$$. $$K(t)$$ is approximated by a sum of exponentials with $\gamma_D = 6.2564$ (a) and $\gamma_D = 6.8$ (b). Curves with label $\gamma$ correspond to $$\Omega = 10^{-3}$$. The dotted lines correspond to results within linear response approximation (6)-(8).
the typical time scales of the system λ₁ and λ₂—stemming from hopping and local motion in the potential well respectively, i.e. [3, 6]

\[ K(t) = \sum_{\nu \in \mathbb{Z}} g_\nu e^{i\nu t}. \]

(8)

The weights \( g_\nu \) are determined by the correlation function \( K(t) \) and its derivatives at \( t = 0 \).

3. GENERATION OF HIGHER HARMONICS

The generation of the \( n \)-th harmonic in the output due to the nonlinearities is characterized by the ratio

\[ \eta_n(\Omega) = \frac{|M_n|^2}{\Delta^2}. \]

(9)

The second harmonic depends on the noise strength as shown for the symmetric and asymmetric case in Fig. 2. In the symmetric case (Fig. 2(a)) a “dip” appears which becomes sharper with decreasing frequencies. In the asymmetric case (Fig. 2(b)) we do not observe such behaviour.

For the third harmonic, \( \eta_3 \), we find a smooth curve in the symmetric case and a dip in the asymmetric case.

We have confirmed the results for the higher harmonics within an adiabatic approximation, valid for small driving frequencies.

4. PHASE SHIFT OF THE OUTPUT SIGNAL

We note that the periodic asymptotic mean value in (3) involves complex-valued Fourier coefficients \( M_\nu \). It is of interest to investigate the behaviour of the corresponding phases, \( \varphi_\nu \), of (3)—which define a characteristic lag of the determinisic phase \( (\Omega t + \varphi) \)—as a function of the parameters characterizing the stochastic resonance. In the following we have numerically studied the behaviour of the phases \( \varphi_1 \) and \( \varphi_2 \) as a function of increasing noise intensity \( \Delta \), with all other parameters kept fixed at values denoted in Fig. 1. In Fig. 3, the phase shifts \( \varphi_\nu \), defined in (3), are shown for the first and second harmonic of the asymptotic mean value \( \langle x(t) \rangle_m \). We again distinguish between the symmetric (Fig. 3(a), (c)) and asymmetric case (Fig. 3(b), (d)). The results within linear response theory are shown by dotted lines. The phase shift \( \varphi_1 \) in the symmetric case looks like in the quartic model: the extremum results from the competition between internal motion and

---

Fig. 2. Higher harmonic \( \eta_n \), parameters as in Fig. 1.
hopping processes. In the asymmetric case the extenuum is suppressed for small frequencies because the hopping disappears at small noise strength.

At values of $D$, for which a dip in a higher harmonic appears, the corresponding phase shift approaches a step function for small driving frequencies $\Omega$. This characteristic behaviour, which cannot be explained on a pure deterministic level (i.e., $D = 0$), still awaits a simple physical intuitive explanation. We hope to be able to shed light onto this open problem in future work.
