(Received 2 November 2011; published 3 January 2012)

We numerically investigate the transport of a suspended overdamped Brownian particle which is driven through a two-dimensional rectangular array of circular obstacles with finite radius. Two limiting cases are considered in detail, namely, when the constant drive is parallel to the principal or the diagonal array axes. This corresponds to studying the Brownian transport in periodic channels with reflecting walls of different topologies. The mobility and diffusivity of the transported particles in such channels are determined as functions of the drive and the array geometric parameters. Prominent transport features, like negative differential mobilities, excess diffusion peaks, and unconventional asymptotic behaviors, are explained in terms of two distinct lengths, the size of single obstacles (trapping length), and the lattice constant of the array (local correlation length). Local correlation effects are further analyzed by continuously rotating the drive between the two limiting orientations.

I. INTRODUCTION

The effective control of mass and charge transport in artificial micro- and nanostructures requires a deep understanding of the diffusive mechanisms involving small objects in confined geometries. Such situations are typically encountered when studying the transport of particles in, e.g., biological cells [1] and zeolites [2], catalytic reactions occurring either on templates or in porous media [3], chromatography or, more generally, separation techniques of size-dispersed particles on micro- or even nanoscales [4]. In many respects these transport phenomena can be regarded as diverse manifestations of geometrically constrained Brownian dynamics in one or higher dimensions [5].

In this paper we focus on the dc driven transport of pointlike Brownian particles in two dimensional (2D) arrays. Restricting the volume of the phase space available to the diffusing particles by means of confining boundaries, or obstacles, causes remarkable entropic effects [6–17]. In quasi-1D geometries (narrow channels), driven transport of charged particles across bottlenecks, such as ion transport through artificial nanopores or biological channels, represents an ubiquitous situation, where diffusion is effectively controlled by entropic barriers [8]. Similarly, the operation of artificial Brownian motors and molecular machines [9,10] also results from the interplay of thermal diffusion and the pinning action by both energetic and entropic barriers.

Higher dimensional geometries have recently attracted broad interest in the context of separation of macromolecules [18], like colloids [19], DNA fragments [20,21], or even magnetic vortices [22–25], because of the occurrence of induced transverse drifts, which separate different objects depending on their bulk diffusivity [26–28]. Such systems are essentially 2D arrays of impenetrable obstacles traversed by diffusing particles subjected to external gradients. An accurate modeling of real experiments, like those cited here and many more, would require incorporating nontrivial effects due to particle interactions [22,27], fluidics [28,29], chaos [30],

inertia [23], excluded volume [5,26], particle shape [31,32], spatial asymmetries, and disorder [9,10], to mention but a few. In other contexts the underlying planar constrained geometries have been modeled also by arrays of traps [33,34], or egg-carton potentials [35,36].

In order to attempt a first quantitative characterization of forced transport across a 2D array, we used a simplified model where a single Brownian particle of negligible size is suspended in an unmovable interstitial fluid at fixed temperature (dilute suspension). The particle is free to diffuse in the connected space delimited by circular reflecting obstacles of finite radius, arranged in a rectangular lattice. The particle is subjected to thermal fluctuations and large viscous damping (as is often the case for biomolecules, colloids, and magnetic vortices [9,10]), and a homogeneous constant force (Fig. 1). Such a dc drive is applied from the outside by coupling the particle to an external field (for instance, by assuming that the particle carries a dielectric or magnetic dipole, or a magnetic flux), without inducing drag effects on the suspension fluid. To simplify our model even further, we neglected any local spatial asymmetry, such as one obtains by lining up noncircular obstacles in symmetric lattices or by arranging circular obstacles in suitable anisotropic arrays [9,10]. Under such conditions the dynamics of the driven particle is fully described by an overdamped 2D Langevin equation, which we encoded in our numerical simulation algorithm, or by the corresponding 2D Fokker-Planck equation, which lends itself to a more systematic analytical treatment [5]. All other effects, including particle-particle and particle-obstacle interactions, hydrodynamic corrections, chaotic and inertial dynamical terms, particle size and shape, are thus ignored.

The properties of Brownian transport in the stationary regime are well quantified by the particle mobility and diffusivity as functions of the external drive (magnitude and orientation) and of the array parameters (obstacle radius and lattice constants). Thanks to the simplifications assumed in the present model, we detected prominent transport features, like negative differential mobilities, excess diffusion peaks,

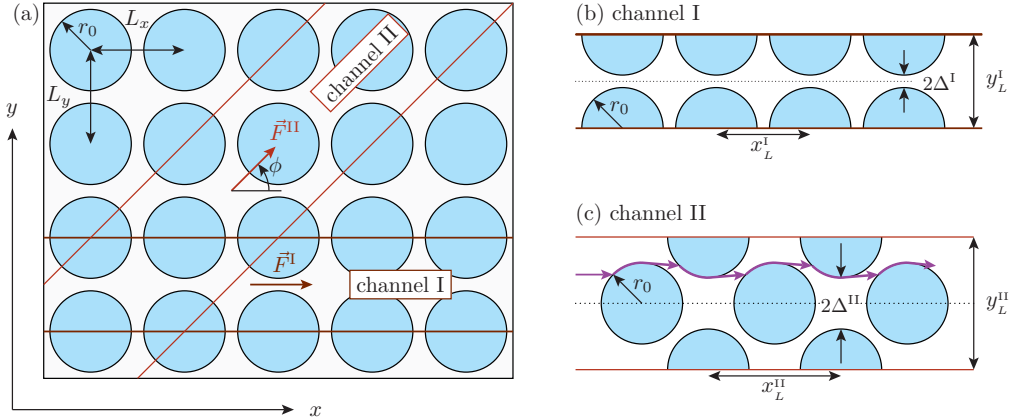

FIG. 1. (Color online) Sketch of a square array, $L_x = L_y$, of circular obstacles with radius r_0 . (a) The Brownian particle is driven by a dc force \vec{F} oriented at an angle ϕ with the horizontal axis. Transport through the array can be reduced to transport along corrugated channels of type I for $F^I, \phi = 0$, and type II for $F^{II}, \phi = \pi/4$, with appropriate compartment sizes. Channels I and II are sketched in (b) and (c), respectively; $y_L^{I,II}$ and $x_L^{I,II}$ denote the width and the periodicity of the channel. The vertical distance between two opposite obstacles is $2\Delta^{I,II} = y_L^{I,II} - 2r_0$. The trajectory drawn in (c) is the limiting noiseless trajectory for $F^{II} \rightarrow \infty$ pointing to the right. The central horizontal lines in (b) and (c) are the channel symmetry axes, which suggest to further reduce the analysis of the problem to half the sketched channels (see Sec. II).

and unconventional asymptotic behaviors, which went unnoticed in earlier reports, experimental and computational alike. We explain the properties of Brownian transport in 2D arrays in terms of two distinct depinning mechanisms: (i) trapping by a single obstacle, which the particle can overcome only by diffusing a transverse distance of the order of the obstacle size, while being driven the same longitudinal length; (ii) correlated collisions against obstacle rows at an angle with the external force, which tend to collimate the particle trajectories to form stream lines connecting and flowing around the obstacles. Such mechanisms correspond to two different length scales, respectively: the obstacle radius (independent of the array geometry) and the effective obstacle spacing (resulting from the combination of array geometry and drive orientation).

This paper is organized as follows. In Sec. II we introduce the Langevin equation formalism employed in our simulation code. We show how for special orientations of the drive the problem can be reduced to the transport in corrugated 1D channels. Mobility and diffusivity data are plotted in Sec. III as functions of the drive, the obstacle radius, and the array lattice constants for two such corrugated channels corresponding, respectively, to orienting the drive along the principal (Sec. III A) and the diagonal axes of a square array (Sec. III B). Mobility and diffusivity dependence on the system parameters are interpreted in Sec. IV in terms of the two aforementioned depinning mechanisms. In Sec. V, local correlation effects due to the array geometry are analyzed in more detail by continuously rotating the drive between the two limiting orientations of Sec. III. Finally, we summarize our results in Sec. VI.

II. MODEL

Let us consider an overdamped Brownian particle of unit mass diffusing in a suspension fluid contained in a 2D rectangular array, $L_x \times L_y$, of reflecting circular obstacles of radius r_0 , as illustrated in Fig. 1(a). The particle is subjected to a homogeneous force \vec{F} oriented at an angle ϕ with the

horizontal axis x . The overdamped dynamics of the particle is modeled by the 2D Langevin equation,

$$\frac{d\vec{r}}{dt} = \vec{F} + \sqrt{D_0}\vec{\xi}(t), \quad (1)$$

where $\vec{r} = (x, y)$ and $\vec{\xi}(t) = (\xi_x(t), \xi_y(t))$ are zero-mean, white Gaussian noises with autocorrelation functions $\langle \xi_i(t)\xi_j(t') \rangle = 2\delta_{ij}\delta(t-t')$, with $i, j = x, y$. The noise strength D_0 corresponds to the particle free or bulk diffusivity in the absence of geometric restrictions and is proportional to the temperature of the suspension fluid. We numerically integrated Eq. (1) by a Milstein algorithm [37]. The stochastic averages reported in the forthcoming sections were obtained as ensemble averages over 10^6 trajectories with random initial conditions; transient effects were estimated and subtracted. To check the reliability of our numerical simulations we solved the corresponding Fokker-Planck equation by means of a finite-element algorithm and obtained a good comparison with the Langevin method.

The driven particle current across the array strongly depends on the force orientation. The problem cannot be reduced to a 1D problem, unless \vec{F} is oriented along a lattice axis, i.e., $\phi = \phi_{n,m}$ with $\phi_{n,m} = \arctan(nL_y/mL_x)$ ($n, m \in \mathbb{Z}$ and $m \neq 0$). Due to its spatial symmetry, the array can then be regarded as consisting of identical periodic channels parallel to \vec{F} and separated by reflecting walls. This allows to interpret the stationary transport properties of the array in terms of transport mechanisms through compartmentalized narrow (quasi-1D) channels. In Fig. 1 we illustrate the two limiting cases with $\phi = 0$ and $\phi = \pi/4$ for a square lattice, $L_x = L_y$. For a rectangular lattice, i.e., $L_x \neq L_y$, and $\phi = 0$, the reduced channels are horizontal and have rectangular compartments, $x_L^I \times y_L^I$ with $x_L^I = L_x$ and $y_L^I = L_y$. For $\phi = \phi_{1,1} = \arctan(L_y/L_x)$, the reduced channels are diagonal and their compartments have width $y_L^{II} = 2L_xL_y/\sqrt{L_x^2 + L_y^2}$ and period $x_L^{II} = \sqrt{L_x^2 + L_y^2}$. For a square lattice, the latter channels coincide with the channel II of Fig. 1(c), where $y_L^{II} = x_L^{II} = L_x\sqrt{2}$. Note that for

symmetry reasons, the discussion of channels I and II can be further simplified by halving the channel width; see Figs. 1(b) and 1(c).

Motivated by these observations we investigated Brownian transport in two categories of reduced periodic channels, conventionally directed along the x axis (and parallel to \vec{F}). They correspond to cutting, respectively, channel I of Fig. 1(b) and channel II of Fig. 1(c) along the central dotted line and then varying the compartment length x_L at will (note that here and in what follows the superscripts are omitted). Channels I are thus characterized by a corrugated and a smooth wall, a geometry that lets straight particle trajectories through, no matter what the radius of the circular obstructions. Channels II have equally corrugated walls, though shifted by half a period; for $r_0 > y_L/4$ the driven particle can cross the channel only by circumventing the obstructions on either walls. As a consequence, one expects distinct transport properties for these two channel geometries [38–42]. Note that tuning the compartment parameters corresponds to investigating rectangular (channels I) and face-centered rectangular arrays in two dimensions (channels II) with \vec{F} parallel to the principal axes.

Two transport quantifiers that best illustrate the different properties of channels I and II are the nonlinear mobility and the effective diffusion coefficient. We characterize the response of a Brownian particle dc driven along the channel axis by computing its mobility μ ,

$$\mu(F) = \langle \dot{x}(F) \rangle / F, \quad (2)$$

where $\langle \dot{x}(F) \rangle = \lim_{t \rightarrow \infty} [\langle x(t) \rangle - x(0)]/t$, and its diffusivity D ,

$$D(F)/D_0 = \lim_{t \rightarrow \infty} [\langle x^2(t) \rangle - \langle x(t) \rangle^2] / 2D_0 t, \quad (3)$$

both as functions of F for different channel geometries. In the absence of external drives, Einstein's relation [43],

$$\mu_0 \equiv \mu(0) = D(0)/D_0, \quad (4)$$

establishes the dependence of the transport quantifiers on the channel geometry and temperature under equilibrium conditions.

For a more compact presentation of our numerical data, we remark that Eq. (1) can be conveniently rewritten in terms of the rescaled units $t \rightarrow tD_0$ and $F \rightarrow F/D_0$. A straightforward dimensional argument shows that both the particle mobility, Eq. (2), and its diffusivity in units of D_0 , Eq. (3), are functions of F/D_0 , only, for any *given* channel geometry.

III. CHANNEL TRANSPORT

Contrary to smoothly corrugated channels, also called entropic channels [8], introduced first in Ref. [6] and further investigated in Refs. [11–15], strongly compartmentalized channels with narrow sharp bottlenecks, or pores, cannot be analyzed in terms of an effective 1D kinetic process directed along their axis [40]. Accordingly, driven transport in such strongly constrained geometries exhibits distinct features which cannot be reduced to known properties of Brownian motion in 1D periodic systems [8,43].

We outline here the main differences between transport in entropic and sharply compartmentalized channels. In entropic

channels $\mu(F)$ *increases* from a relatively small value for $F = 0$, μ_0 of Eq. (4), up to the free-particle limit, $\mu_\infty = 1$, for $F \rightarrow \infty$ [14,15]. On the contrary, in coaxial compartmentalized channels $\mu(F)$ *decreases* monotonically with increasing F toward a geometry-dependent asymptotic value μ_∞ , equal to the ratio of the pore to the channel cross section [40]. Such an asymptote vanishes for eccentric compartmentalized channels with off-axis, nonoverlapping pores [42].

Significant differences have also been reported for the diffusivity. For entropic channels with smooth pores, the function $D(F)$ approaches the free-diffusion limit for $F \rightarrow \infty$, $D(\infty) = D_0$, after going through an excess diffusion peak centered at an intermediate (temperature dependent [14,15]) value of the drive. Such a peak signals the depinning of the particle from the entropic barrier array [44]. In coaxial compartmentalized channels, instead, $D(F)$ exhibits a distinct quadratic dependence on F [39,41], reminiscent of Taylor's diffusion in hydrodynamics. This observation suggests that the particle never frees itself from the geometric constriction of the compartment pores, no matter how strong F . The quadratic divergence $D(F)$ can be cut off for suitably large F by alternately shifting the pores off-axis (eccentric channels [42]).

Driven transport in channels I and II of Fig. 1 is characterized by the superposition of, or sometimes the competition between, the properties observed for the two opposite compartmentalization geometries considered in the earlier literature. We remind here that, due to the mirror symmetry of the obstacle geometries of Figs. 1(b) and 1(c), our analysis refers to the irreducible channels I and II obtained by cutting the channels sketched there along their axis (dotted line) and then varying their spatial periodicity. Therefore the irreducible channels discussed below have effective width $y_L/2$ and transverse bottleneck width $\Delta = y_L/2 - r_0$.

A. Channels I

Channels I corresponding to square arrays, $x_L = y_L$, exhibit transport properties apparently not much different from the entropic channels. In particular, the mobility is an increasing function of F ; the $\mu(F)$ curves jump from μ_0 to $\mu_\infty = 1$ sharper and sharper as the radius r_0 of the obstacles is increased [Fig. 2(a)]. The diffusivity curves develop an excess diffusion peak in correspondence with the mobility surge; the height of these peaks weakly depend on r_0 .

New features start to emerge when we consider channels with rectangular compartments, i.e., $x_L > y_L$. These become apparent in Fig. 3, where we display data for simulated transport in channels I for different period lengths x_L . The occurrence of two distinct diffusion mechanisms is proved by the two-step increase of the mobility and the corresponding double diffusivity peaks. Such peaks merge as x_L tends to y_L .

B. Channels II

In Fig. 4 we plot the curves $\mu(F)$ and $D(F)$ for channels II with comparable compartment dimensions x_L and y_L and different obstacle radius r_0 . The mobility function $\mu(F)$ develops a nonmonotonic dependence on F , which becomes prominent for narrow bottleneck widths, $\Delta = y_L/2 - r_0$, but vanishes altogether for $\Delta \geq y_L/4$ [Fig. 4(a)]. Negative differential

FIG. 2. (Color online) Driven transport in channel I with $x_L = y_L = 1$, $D_0 = 0.03$, and different r_0 : particle mobility μ (a) and scaled diffusivity D/D_0 (b) vs the scaled force F/D_0 . Inset: mean exit time through four pores, τ_4 , and two opposite pores, τ_2 . The numerical data are compared with the analytical predictions in Eq. (8).

mobility is a peculiar feature of all sharp compartmentalized channels [40] and eccentric channels, in particular [42]. Indeed, each compartment of the reduced channels II of Fig. 2(c) has two off-axis bottlenecks, located alternately against its top and bottom wall. The subsequent mobility surge toward a horizontal asymptote with $\mu_\infty < 1$ indicates that on increasing F the particle grows more sensitive to the pinning action of the obstacles, which it overcomes initially by mere Brownian diffusion and eventually with the assistance of the drive itself.

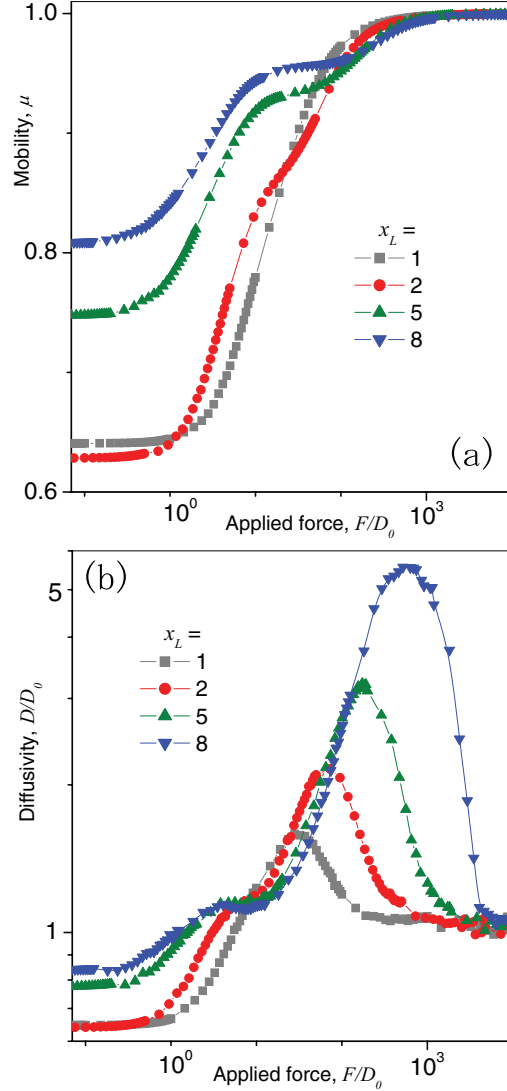

FIG. 3. (Color online) Driven transport in a channel I: particle mobility μ (a) and scaled diffusivity D/D_0 (b) vs the scaled force F/D_0 for different x_L . Other simulation parameters are $y_L = 1$, $D_0 = 1$, and $r_0 = 0.4$.

Correspondingly, such change in the depinning mechanism is signaled by a conspicuous diffusion peak [Fig. 4(b)]. In comparison to Fig. 2(b), here the $D(F)$ peaks are more than one order of magnitude larger than D_0 and their position strongly depends on Δ (or r_0). Most remarkably, the asymptote $D(\infty)$ is systematically larger than the free diffusivity D_0 for $\Delta \leq y_L/4$, like for eccentric compartmentalized channels [42]. Note also that the slowly increasing branches of the curves plotted in Fig. 4(b) tend to overlap and grow slower than for coaxial compartmentalized channels, where $D(F)$ diverges like F^2 [39,42].

Like for channels I, two different transport mechanisms become apparent as we space the circular obstacles out along the channel axis, i.e., for $x_L \gg y_L$. The diffusivity curve $D(F)$ develops a secondary peak at lower F , which grows prominent on further increasing x_L [Fig. 5(b)]. At variance with the high- F peak, the position of the emerging peak is rather insensitive to x_L . Correspondingly, the mobility curves shift

FIG. 4. (Color online) Driven transport in a channel II with $x_L = 2$, $y_L = 1$, $D_0 = 0.03$, and different r_0 : particle mobility μ (a) and scaled diffusivity D/D_0 (b) vs the scaled force F/D_0 . Dotted lines represent μ_∞ , Eq. (9), in (a) and D_∞ , Eq. (10), in (b).

toward higher values, their most apparent feature remaining its nonmonotonic F dependence. By closer inspection, for large x_L , in correspondence with the secondary $D(F)$ peak one notices the appearance of a shoulder, or step, on the low- F raising branch of $\mu(F)$.

IV. DEPINNING MECHANISMS

The most remarkable property of transport in channels I and II emerges for rectangular compartments with $x_L > y_L$. As anticipated in Secs. III A and III B, the two-peaked structure of $D(F)$ results from the competition between the two depinning mechanisms illustrated in Fig. 6. The Brownian particle overcomes the obstacle thanks to the combined action of the drive F and the noise $\xi(t)$. The drive, in particular, on one side pushes the particle against the obstacles, thus enhancing the low- F pinning by the array [raising $D(F)$ branch], on the other side guides the particle around the obstacles, so as to collimate its trajectories through a coaxial [channels I,

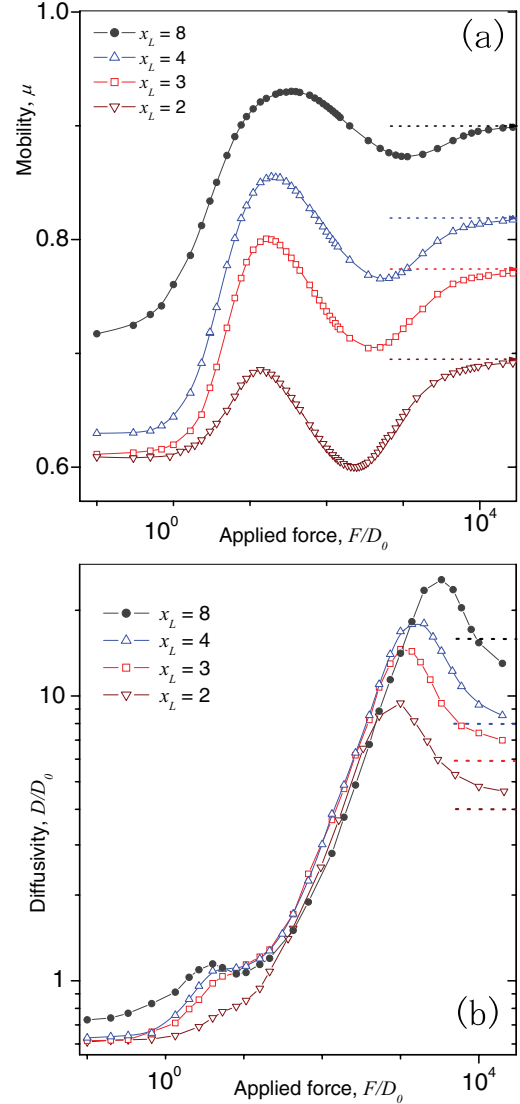

FIG. 5. (Color online) Driven transport in a channel II with $y_L = 1$, $D_0 = 0.03$, $r_0 = 0.4$, and different period x_L : particle mobility μ (a) and scaled diffusivity D/D_0 (b) vs the scaled force F/D_0 . Dotted lines represent μ_∞ , Eq. (9), in (a) and D_∞ , Eq. (10), in (b).

$D(\infty) = D_0$) or eccentric sequences of bottlenecks [channels II, $D(\infty) > D_0$].

For relatively low drives, the particle circumvents a single circular obstacle, irrespective of the array geometry and the drive orientation, by *diffusing* a transverse distance r_0 over the time it takes to *drift* the same distance r_0 [Fig. 6(a)]. On equating the transverse diffusing time, $\tau_\perp = r_0^2/2D_0$, and the longitudinal drift time, $\tau_\parallel = r_0/F$, we locate the low- F depinning threshold at

$$F^{(1)}/D_0 = 2/r_0. \quad (5)$$

We recall that excess diffusion peaks are characteristic signatures of depinning thresholds [9,44]. We stress that this estimate for $F^{(1)}$ is expected to apply to both types of channels, I and II, and to any geometry and size of their compartments (i.e., to any 2D array). As shown below, in the case of square compartments, Figs. 2(b) and 4(b), low- and high- F peaks cannot be separated. The estimate of Eq. (5) closely locates

FIG. 6. (Color online) Depinning mechanisms. (a) The Brownian particle circumvents a single obstacle by diffusing in the transverse direction (vertical arrows) and then drifting along the axis driven by F (horizontal arrow). (b), (c) Trajectory focusing along the channel lane results from the competing action of longitudinal drift (horizontal arrows) and transverse diffusion (vertical arrows) across the array. The transverse diffusion length is of the order of half the channel width in (b) and half the bottleneck width in (c). (d) Example of minimum longitudinal mobility orientation in a rectangular 2D array; see Sec. V.

the low- F peaks of all $D(F)$ curves reported in Figs. 3(b) and 5(b). Note that in the limit of narrow bottlenecks, $\Delta \rightarrow 0$, $F^{(1)}/D_0$ approaches $4/y_L$, irrespective of x_L [Fig. 5(b)].

For large drives, channels I and II behave differently. The bottlenecks in channels I are coaxial [Fig. 6(b)]. This means that the driven Brownian particle gets trapped within a couple of obstacles if, during the *drift* time it takes to cover the distance separating the center of a bottleneck from the nearest pair of obstacles, $x_L - r_0$, it *diffuses* a transverse distance of the order of half the width of the (reduced) channel, $y_L/4$. Equating the corresponding times, $\tau_{\perp} = y_L^2/32D_0$ and $\tau_{\parallel} = (x_L - r_0)/F$, we obtain an estimate for the position of the high- F diffusivity peaks in channels I, namely,

$$F^{(2,I)}/D_0 = 32(x_L - r_0)/y_L^2. \quad (6)$$

In channels II with $\Delta < y_L/4$, i.e., $r_0 > y_L/4$, the focusing action of the drive forces the particle through a meandering path. This action becomes effective when the particle *drifts* the distance separating a bottleneck from the opposing obstacle [Fig. 6(c)], $x_L/2 - r_0$, while *diffusing* across the lane passing through the bottleneck of a (reduced) channel, i.e., a transverse distance of the order of half its width, $\Delta/2$. The corresponding depinning threshold is thus estimated to be

$$F^{(2,II)}/D_0 = 4(x_L - 2r_0)/\Delta^2. \quad (7)$$

Contrary to $F^{(1)}$, the thresholds $F^{(2,I)}$ and $F^{(2,II)}$ depend on the channel geometry, being different for channels I and II, and linearly shift to higher values with increasing the length of the channel compartments x_L , or shrinking the obstacle size r_0 . Despite the rough estimate of the characteristic transverse diffusing length, the thresholds of Eqs. (6) and (7) locate quite closely the large drive diffusion peaks in panels (b) of Figs. 2–5. For square channel compartments, $x_L = y_L$, with narrow bottlenecks, $r_0 \simeq y_L/2$, the two depinning mechanisms are not clearly distinguishable, being the size of the obstacle and the array lattice constant of the same order. Correspondingly, the diffusivity curves exhibit only one peak.

The limiting values of $\mu(F)$ and $D(F)$ for $F = 0$ and $F \rightarrow \infty$ are also of some interest. For $F = 0$, mobility and diffusivity are related through Einstein's identity, Eq. (4). Analytical expression for μ_0 in restricted geometries can be obtained only under special conditions [38,41]. For instance, in channels I and II corresponding to *square* arrays with narrow bottlenecks, $\Delta \rightarrow 0$, μ_0 can be expressed in terms of the mean first exit time for the Brownian particle to escape the interstitial region delimited by four nearest neighboring obstacles [Fig. 2(b), inset]. Our numerical simulations show that, as expected, the mean exit time through all four openings, τ_4 , is half the mean exit time through any pair of opposite openings, τ_2 , with both τ_2 and τ_4 decaying inversely proportional to the pore width, i.e., like $1/\sqrt{\Delta}$. These results are well fitted by the law

$$\tau_2 = 2\tau_4 \simeq \left(1 - \frac{\pi}{4}\right) \frac{x_L^2 \pi}{8D_0 \sqrt{\Delta/x_L}}, \quad (8)$$

which is consistent with a recent analytical prediction [see Eq. (13) of Ref. [45]]. Moreover, the mean sojourn time in a square channel I compartment is $2\tau_2$ and, accordingly, $\mu_0 = x_L^2/4D_0\tau_2$, also in close agreement with the numerical data for small Δ plotted in Fig. 2. This argument can be easily generalized to rectangular arrays, as long as the distance between neighboring obstacles remains sufficiently small compared to the lattice constants.

The asymptotes $\mu(\infty)$ and $D(\infty)$ in channels II with $\Delta < y_L/4$ also deserve attention. In the limit $F \rightarrow \infty$, the pore eccentricity, which is responsible for the *negative differential mobility* of channels II, is eventually superseded by the funneling effect due to the rounded shape of the obstacles. In such limit, the particle trajectories consist of straight parallel segments, which a free particle traverses with speed F , and arcs of the obstacle boundaries, as shown in Fig. 1(c), where the driven particle slows down. On averaging out noise fluctuations, the total time taken by the particle to cross one channel compartment, τ_c , can be derived analytically, so that, $\mu_{\infty} = x_L/\tau_c F$, that is

$$\mu_{\infty} = \left[1 - \frac{y_L}{x_L} \sqrt{2\epsilon - 1} + \frac{r_0}{x_L} \ln \frac{\epsilon + \sqrt{2\epsilon - 1}}{\epsilon - \sqrt{2\epsilon - 1}}\right]^{-1}, \quad (9)$$

with $\epsilon = 2r_0/y_L$ and $1/2 < \epsilon < 1$. The predicted values for μ_{∞} are indicated by dotted lines in Figs. 4(a) and 5(a). Note that in channels II for $\Delta \geq y_L/4$ and in all channels I the traversal time is $\tau_c = x_L/F$ and therefore $\mu_{\infty} = 1$.

A full analytic calculation of $D(\infty)$ proved to be a cumbersome task. As in channels II each bottleneck is faced by a blocking obstacle, one would expect that for $\Delta < r_0$ the diffusivity $D(\infty)$ scales like r_0/Δ , namely the ratio of the obstacle diameter to the vertical distance between two neighboring obstacles. Furthermore, on regarding the channel as a 1D discretized structure with spatial constant x_L , one can formally express $D(\infty)$ as $x_L^2/2\bar{\tau}$, where $\bar{\tau}$ is a certain diffusion time constant, which we know to be proportional to the compartment volume [45]. Hence even without calculating $\bar{\tau}$, one concludes that $D(\infty)$ is proportional to x_L . Therefore we tried to reproduce our numerical data for $D(\infty)$ by means

of the heuristic law

$$\frac{D(\infty)}{D_0} = \frac{x_L r_0}{2y_L \Delta}, \quad (10)$$

which turns out to work well both in Fig. 4(b) and in Fig. 5(b). Note that, in the case of larger x_L , Fig. 5(b), where Eq. (10) seems to work not as well, a conclusive estimate of the asymptote $D(\infty)/D_0$ would require simulating even higher F/D_0 values, which in practice becomes very difficult to implement numerically because this regime would require exceedingly small time steps.

V. PARALLEL AND LATERAL TRANSPORT

We address now the practical situation [18–23,25–29] when the orientation of the drive can be varied at will with respect to the array principal axes. The angle ϕ in Fig. 1(a) can thus be rotated between 0 and $\pi/2$. For a square lattice, $L_x = L_y$, this corresponds to continuously switch from a channel I ($\phi = 0$) to a channel II ($\phi = \pi/4$) and then back again to the initial channel I geometry ($\phi = \pi/2$). For a rectangular 2D lattice, $L_x \neq L_y$, the two channels I have different width, that is, L_y for $\phi = 0$ and L_x for $\phi = \pi/2$, while no channel II is recovered. Indeed, as \vec{F} is directed along a diagonal of the rectangular lattice cell, the corresponding reduced 1D channel looks similar to channel II in Fig. 1(c), but for a relative shift of the lower and upper obstacle rows. The transport properties of such diagonal channels are qualitatively the same as for channels II of Sec. III B.

In Fig. 7 we display some significant simulation data for driven Brownian transport in square and rectangular arrays. To this purpose we generalized the definitions of Eqs. (2) and (3) to extract the mobility and the diffusivity in the direction parallel and orthogonal to \vec{F} . The corresponding four transport quantifiers are denoted by μ_{\parallel} , D_{\parallel} for the longitudinal transport and by μ_{\perp} , D_{\perp} for the lateral or transverse transport.

The salient properties of directed transport in 2D arrays are easily reconciled to the geometric properties of the particular system at hand. With focus on the ϕ dependence of the transport quantifiers, one notices the following:

(i) For square arrays and vanishingly small drives, $D_{\perp}(0) = D_{\parallel}(0)$ and $\mu_{\perp}(0) = \mu_{\parallel}(0)$, irrespective of ϕ . This is consistent with the D_4 symmetry of the array lattice and with the fact that the mobility and diffusivity components are defined in the long-time limit. Applying a finite drive to a square array breaks the D_4 symmetry and leads to weaker angular symmetry relations, $D_{\parallel,\perp}(\psi) = D_{\parallel,\perp}(-\psi)$, $\mu_{\parallel}(\psi) = \mu_{\parallel}(-\psi)$, and $\mu_{\perp}(\psi) = -\mu_{\perp}(-\psi)$, where $\psi = \phi - \pi/4$. Note that the lateral mobility is an odd function of ψ , all other transport quantifiers being even functions.

(ii) Driven longitudinal transport in a *square* array is the least efficient for two special orientations, $\pm\psi^*$, or ϕ^* and $\pi/2 - \phi^*$, as signaled by the occurrence of two symmetric dips in μ_{\parallel} and peaks in D_{\parallel} and D_{\perp} [Figs. 7(b) and 7(c)]. The lateral mobility μ_{\perp} vanishes for $\phi = 0, \pi/2$ (channel I geometry) and in correspondence with the diffusion peaks, $\psi = \pm\psi^*$. The interpretation of such angular dependence follows from the argument leading to Eq. (9). A noiseless driven trajectory consists of straight segments parallel to \vec{F} and circular arcs

FIG. 7. (Color online) Angular effects. (a) Migration angle; (b) longitudinal, μ_{\perp} , and lateral mobility, μ_{\parallel} ; and (c) scaled longitudinal, D_{\perp}/D_0 , and lateral diffusivity, D_{\parallel}/D_0 , of a Brownian particle driven at an angle ϕ in rectangular arrays with different L_x (see legends). All quantities are plotted vs ϕ for $L_y = 1$, $r_0 = 0.4$, and $F/D_0 = 10^3$. In these simulations we set $D_0 = 1$.

running around the obstacles. Each straight segment is tangent to the circumvented obstacle and impinges on the next obstacle that stands on the particle's way. The blocking action of this second obstacle is the largest, i.e., μ_{\parallel} has a minimum, when the incident segment runs along one of its diameters [Fig. 6(d)]. Under these circumstances, the trajectory can run around the blocking obstacle on either side with equal probability, i.e., $\mu_{\perp} = 0$, and the dispersion of the transport current in both directions, i.e., D_{\parallel} and D_{\perp} , is maximum. For narrow bottlenecks a simple calculation yields $\phi^* = \arccos \sqrt{1 - (r_0/L_y)^2}$, in agreement with the plots of Fig. 7.

(iii) The lateral diffusivity in driven arrays is suppressed for increasing F (not shown). This effect signals that the particle is effectively channeled by oriented rows of bottlenecks [possibly at an angle with \vec{F} , see Fig. 7(a)]. Such mechanism sets on when the driven particle crosses an array unit cell in a time much shorter than the time it takes to diffuse across a single bottleneck. The effective migration angle [28], α , of a particle driven across a 2D array does not necessarily coincide with the drive orientation. In fact, $\alpha = \phi + \arctan(\mu_{\perp}/\mu_{\parallel})$. This means that α and ϕ coincide only for $\mu_{\perp} = 0$, that is for $\psi = \pm\psi^*$ and $\pm\pi/4$. For a square lattice the angular dependence of $\alpha(\phi)$ is plotted in Fig. 7(a). Due to the angular symmetry of μ_{\perp} and μ_{\parallel} , it follows that $\alpha(\psi) + \alpha(-\psi) = \pi/2$. The steplike structure of $\alpha(\phi)$ is controlled by the commensuration of the lattice constants, as first reported in Ref. [28].

(iv) For rectangular arrays, the angular symmetries of the transport quantifiers in (i)–(iii) are broken. The nodes of the curves $\mu_{\perp}(\phi)$ plotted in Fig. 7(b) increase in number with the ratio L_x/L_y . Indeed, reflecting the lower rotational lattice symmetry, there exist more distinct critical angles ϕ^* that satisfy the maximal blocking condition of item (ii). However, as L_x grows much longer than L_y , the lateral mobility for $\phi < \pi/4$ gets suppressed, because channeling in the horizontal direction becomes more effective than in the vertical direction. Correspondingly, the migration angle $\alpha(\phi)$ develops more steps. For commensurate lattice constants, i.e., $L_x/L_y = n$ with n an integer, we counted exactly n steps of the $\alpha(\phi)$ curves within the interval $0 < \phi \leq \pi/4$, each corresponding to a node of $\mu_{\perp}(\phi)$. For $\pi/4 < \phi \leq \pi/2$, the step and node structure are smeared out when increasing the radius of the obstacles. Eventually, in the limit $L_x \gg L_y$, lateral transport is appreciable only for $\phi > \pi/2 - \phi^*$. Under such drive conditions, the curve $\mu_{\perp}(\phi)$ boils down to a broad peak, which is seemingly independent of L_x . Correspondingly, the longitudinal mobility μ_{\parallel} is suppressed and the longitudinal diffusivity grows orders of magnitude larger than D_0 .

VI. SUMMARY

Forced transport across a 2D array was investigated for a simplified model where a single overdamped Brownian

particle of negligible size is suspended in an unmovable interstitial fluid at fixed temperature. The particle is free to diffuse in the connected space delimited by circular reflecting obstacles of finite radius, arranged in a rectangular lattice. The particle is only subject to thermal fluctuations and a homogeneous constant driving force.

Brownian particle transport in the stationary regime was investigated by analyzing the dependence of the particle mobility and diffusivity on the external drive (magnitude and orientation) and the array geometry (obstacle radius and lattice constants). Interesting transport properties, including negative differential mobility, excess diffusion peaks, and unconventional asymptotic behaviors, have been detected by means of extensive numerical simulations. Such properties have been explained in terms of two distinct depinning mechanisms: (i) trapping by a single obstacle, and (ii) correlated collisions against obstacle rows at an angle with the external force. The corresponding length scales have been identified to be, respectively, the obstacle radius (independent of the array geometry) and the effective obstacle spacing (resulting from the combination of array geometry and drive orientation).

All other effects, including asymmetry of the obstacles and of their spatial arrangement, particle-particle and particle-obstacle interactions, hydrodynamic corrections, chaotic and inertial dynamical terms, particle size and shape, have been ignored in this paper. The generalization of our analysis to incorporate inertia and hydrodynamic corrections is the next step of this research project.

Despite the various approximations and simplifications discussed above, the effects investigated here are robust enough to challenge experimenters investigating the diffusion of extended objects [20,21,25,26,31,33,46] or even pointlike charge carriers [47] in 2D arrays. Moreover, the interplay of different diffusion length scales has been recently invoked also to explain certain features of the long-time self-diffusion of spherical tracer particles in periodic porous nanostructures [48].
