Charge ordering in the low-temperature monoclinic structure of iron oxoborate (Fe$_2$OBO$_3$) is investigated using the local spin density approximation (LSDA) + $U$ method. While the difference between $t_{2g}$ minority occupancies of Fe$^{2+}$ and Fe$^{3+}$ cations is large and gives direct evidence for charge ordering, the static “screening” is so effective that the total 3$d$ charge separation is rather small. The occupied Fe$^{2+}$ and Fe$^{3+}$ cations are ordered alternately within the chain which is infinite along the $a$ direction. The charge order obtained by LSDA+$U$ is consistent with observed enlargement of the $\beta$ angle. An analysis of the exchange interaction parameters demonstrates the predominance of the interribbon exchange interactions which determine the whole $L$-type ferrimagnetic spin structure.

I. INTRODUCTION

Transition metal compounds with interplay of spin, orbital, and charge degrees of freedom are of strong current interest. Thus, magnetite (Fe$_3$O$_4$), the famous lodestone, is one of the classical examples of such a system, where a first-order metal-insulator transition occurs at $\sim$120 K. According to Verwey this transition is caused by the ordering of Fe$^{2+}$ and Fe$^{3+}$ cations on the octahedral $B$ sublattice of the inverted spinel structure $AB_2$O$_4$. Recently, the local spin density approximation (LSDA) + $U$ method has been used for investigation of the low-temperature monoclinic structure of Fe$_3$O$_4$. The charge and orbitally ordered insulating ground state with two different order parameters: small for the charge and large for the orbital order was obtained self-consistently. While the first order parameter was introduced as the total 3$d$ charge separation between Fe$^{2+}$ and Fe$^{3+}$ cations, the latter one corresponds to the charge difference between occupancies of occupied $t_{2g}$ orbital of Fe$^{2+}$ and unoccupied $t_{2g}$ orbital of Fe$^{3+}$ cations. But an important issue, which is still unresolved is whether the charge ordering in magnetite is driven by Coulomb repulsion between the charges, or by the strain arising from electron-lattice interactions. An analysis of the charge and orbital order parameters in Fe$_3$O$_4$ inevitably results in a strong interplay between Jahn–Teller effect and electrostatic repulsion between electrons. Therefore, theoretical investigations of the isostructural iron and manganese oxoborate (Fe$_2$OBO$_3$ and Mn$_2$OBO$_3$, correspondingly) that support predominantly electrostatic and Jahn–Teller distortion driven mechanisms behind the charge ordering in the same structural arrangement, are highly desirable.

Iron borate (Fe$_2$OBO$_3$) is a semi-valent oxide. It belongs to the homometallic warwickite family with formal chemical formula $MM'$OBO$_3$, where $M$ and $M'$ are, respectively, a divalent and trivalent metal ions. Surprisingly, that the homometallic ($M=M'$) warwickites are known only for Fe$^{12,13}$ and Mn$^{14,15}$. In both compounds the metal have octahedral coordination. These octahedra share edges to form ribbons of four infinite along crystallographic $a$ direction chains of octahedra linked by corner sharing and the trigonal BO$_3$ groups (see Fig. 1).

There are two crystallographically inequivalent sites of the metal ions Fe(1) and Fe(2). Fe$_2$OBO$_3$ is $L$-type ferrimagnetic with drastically smaller in comparison to Fe$_3$O$_4$ critical temperature of $T_c \approx 155$ K, the Fe(1) magnetic moments being aligned antiparallel to the Fe(2) moments. It is almost antiferromagnetic but a small ferrimagnetic moment of $\sim 0.03 \mu_B$ per Fe atom in a 0.05 T field was found. At room temperature Fe$_2$OBO$_3$ is a semiconductor with a thermoactivated conductivity low $\sim E_0/kT$ with $E_0 \approx 0.35$ eV. Upon further heating a broad semiconductor-to-semiconductor transition occurs at $T_{co}$. The $L$-type ferrimagnetic spin structure of Fe$_2$OBO$_3$ is investigated using the local spin density approximation (LSDA) + $U$ method. While the difference between $t_{2g}$ minority occupancies of Fe$^{2+}$ and Fe$^{3+}$ cations is large and gives direct evidence for charge ordering, the static “screening” is so effective that the total 3$d$ charge separation is rather small. The occupied Fe$^{2+}$ and Fe$^{3+}$ cations are ordered alternately within the chain which is infinite along the $a$ direction. The charge order obtained by LSDA+$U$ is consistent with observed enlargement of the $\beta$ angle. An analysis of the exchange interaction parameters demonstrates the predominance of the interribbon exchange interactions which determine the whole $L$-type ferrimagnetic spin structure.

FIG. 1. The Fe$_2$OBO$_3$ structure projected on (100) plane ($b$ vertical, $c$ horizontal). Two structurally distinct Fe(1)O$_6$ and Fe(2)O$_6$ octahedra shown by light and dark sharing, respectively. Plus and minus signs indicate the relative orientation of the moments within each Fe(1) and Fe(2) chains in the magnetically ordered phase.
The low-temperature P121/1 phase of Fe2OBO3. The corresponding P21/c unit cell contains four Fe2OBO3 formula units. We used atom coordinates from Table I of Ref. 11 and the cell parameters \( a = 3.1688 \, \text{Å}, \, b = 9.3835 \, \text{Å}, \, c = 9.2503 \, \text{Å}, \) and \( \beta = 90.22^\circ \) refined at 3 K.\(^{11,13}\) The radii of muffin-tin spheres were taken \( R_{\text{Fe}} = 2.5 \, \text{a.u.}, \) \( R_{\text{O}} = 1.7 \, \text{a.u.}, \) and \( R_{\text{O}(1,2,3,4,5)} = 1.8 \, \text{a.u.} \) Seven kinds of empty spheres were introduced to fill up the interatomic space. For simplicity we neglect small spin-orbit coupling (for instance, in other iron oxide, in Fe3O4, the spin-orbital interaction for 3d electrons was found to be negligibly small). We consider only a collinear spin case, in which the Fe magnetic moments are aligned along the \( a \) direction (see Table I of Ref. 13), which is in a reasonably good agreement with the experimental magnetic structure of Fe2OBO3 below \( T_c \).

### III. LSDA BAND STRUCTURE

The present band structure calculations have been carried out for the low-temperature monoclinic structure of Fe2OBO3. The corresponding P21/c unit cell contains four Fe2OBO3 formula units. We used atom coordinates from Table I of Ref. 11 and the cell parameters \( a = 3.1688 \, \text{Å}, \, b = 9.3835 \, \text{Å}, \, c = 9.2503 \, \text{Å}, \) and \( \beta = 90.22^\circ \) refined at 3 K.\(^{11,13}\) The radii of muffin-tin spheres were taken \( R_{\text{Fe}} = 2.5 \, \text{a.u.}, \) \( R_{\text{O}} = 1.7 \, \text{a.u.}, \) and \( R_{\text{O}(1,2,3,4,5)} = 1.8 \, \text{a.u.} \) Seven kinds of empty spheres were introduced to fill up the interatomic space. For simplicity we neglect small spin-orbit coupling (for instance, in other iron oxide, in Fe3O4, the spin-orbital interaction for 3d electrons was found to be negligibly small). We consider only a collinear spin case, in which the Fe magnetic moments are aligned along the \( a \) direction (see Table I of Ref. 13), which is in a reasonably good agreement with the experimental magnetic structure of Fe2OBO3 below \( T_c \).

The LSDA calculations give only a metallic ferrimagnetic solution without charge separation where partially filled bands at the Fermi level originate from the \( t_{2g} \) orbitals of Fe cations (see Fig. 2).

The lower part of the valence band (below \(-3.5 \, \text{eV}\)) is mainly formed by \( O \) 2p states with a bonding hybridization with Fe 3d states. Fe 3d states give predominant contribution to the bands at \(-3.5 \, \text{eV}\) below and up to 2.5 eV above the Fermi level. The exchange splitting between the spin-up and
spin-down Fe 3d states is roughly 3 eV. Additionally, the fivefold 3d levels are split by the crystal field into \( t_{2g} \) and \( e_g \) subbands. The oxygen octahedra in Fe$_2$OBO$_3$ are strongly distorted and the local symmetry of Fe sites is, of course, lower than cubic. Nevertheless, the cubic component of the ligand field, which is determined by the relative strength of Fe d-O p hybridization of \( \pi \) and \( \sigma \) type, remains dominant, whereas the splitting within \( "t_{2g}" \) and \( "e_g" \) subbands is smaller than the corresponding bandwidth. This allows one to label the corresponding states as \( t_{2g} \) and \( e_g \). The crystal field splitting is roughly 2 eV, which is less than the exchange splitting. This is consistent with the high-spin state of the Fe cations. The symmetry inequivalence of Fe(1) and Fe(2) sites leads to an inexact cancellation of magnetic moments and results in a small ferrimagnetic moment of \(-0.31 \mu_B\) per formula unit. The absolute values of magnetic moments obtained by LSDA are 3.54 \( \mu_B \) and 3.81 \( \mu_B \) for Fe(1) and Fe(2) sites, respectively.

Fe(1) and Fe(2) \( t_{2g} \) and \( e_g \) states with the opposite spin projections share nearly the same energy intervals. Thus, Fe 3d states between \(-3.5 \) and \(-2.0 \) eV originate predominantly from majority spin Fe(1) and minority spin Fe(2) \( t_{2g} \) states whereas the states between \(-2.0 \) and \(-0.5 \) eV are mainly of \( e_g \) character. Partially occupied bands crossing the Fermi level are formed by majority spin Fe(1) and majority spin Fe(2) \( t_{2g} \) states. The nominal occupation of these bands is 1/6. In the majority spin channel, however, the Fe(2) \( t_{2g} \) state, that is oriented in the plane perpendicular to the shortest Fe(2)-O bond, forms quasi-one-dimensional bands with a strong dispersion along the \( a \) direction. The one-dimensional character of the dispersion is explained by the fact that there are only two nearest neighbors of the same kind around each Fe(2) ion. The other two Fe(2) \( t_{2g} \) states are shifted to higher energy and the corresponding bands are completely unoccupied. As a result, the majority spin bands crossing the Fermi level turn out to be half-filled. An Fe(1) ion, in contrast to Fe(2) one, has four Fe(1) neighbors at close distances. As a result of the hybridization between Fe(1) \( t_{2g} \) states the situation in the minority spin channel is more complicated. Twelve \( t_{2g} \) bands are split into three groups of four bands each. The Fermi level is crossed by lowest bands which show a rather strong dispersion along the \( a \) direction but with a period two times smaller than the quasi-one-dimensional Fe(2) bands.

It should be noted that in contrast to experimental data\(^{11,17,18}\) LSDA predicts Fe$_2$OBO$_3$ to be metallic with substantial magnetic moment per unit cell. Apparently, the electron-electron correlations, mainly in the 3d shell of Fe cations, play a significant role.

IV. LSDA+\( U \) RESULTS AND CHARGE ORDERING

To proceed further we take into account the strong electronic correlations in Fe 3d shell using the LSDA+\( U \) method. The calculations have been performed for the \( P2_1/c \) unit cell as well as for double \((2a \times b \times c)\) and triple \((3a \times b \times c)\) \( P2_1/c \) supercells of Fe$_2$OBO$_3$ (without putting in any additional local displacements of oxygen atoms around of Fe$^{2+}$/Fe$^{3+}$ sites). For the \(2a \times b \times c \) supercell the LSDA +\( U \) calculations using the classical value of Coulomb (\(U=5.5\) eV) and exchange (\(J=1\) eV) interaction parameters for Fe result in an insulating charge ordered (CO) solution with an energy gap of 0.13 eV. This is in a strong contrast to metallic solution without CO obtained by the LSDA. The CO pattern obtained from the calculations is similar to the one proposed in Ref. 11. This is a notable result because the CO is not implicit in the atomic coordinates, and it shows that LSDA+\( U \) calculations can assist experiments in revealing CO arrangements. To obtain a reasonably good agreement of the calculated gap of 0.39 eV with experimental value of 0.35 eV we increase the \( U \) value up to 5.5 eV (see Fig. 3). It does not exceed 10\% of the \( U \) value, which is in an accuracy of the \( U \) calculation. Note, however, that the CO obtained by LSDA+\( U \) within \(2a \times b \times c \) supercell does not depend on the \( U \) value of 5-5.5 eV. Here and in the following all results are presented for the double along \( a \) direction \( P2_1/c \) supercell of Fe$_2$OBO$_3$. After self-consistency each of two groups of Fe(1) and Fe(2) atoms is split out in two subgroups of 2+ and 3+ Fe cations with equal number of 2+ and 3+ cations. Thus, one of \( t_{2g} \) majority/minority spin states of Fe(2)/Fe(1) atom becomes completely occupied, whereas all other \( t_{2g} \) states are pushed by strong Coulomb interaction at the energies above 3 eV. The gap is opened between occupied and unoccupied \( t_{2g} \) states of Fe(1)$^{2+}$ and Fe(1)$^{3+}$ for spin-down and Fe(2)$^{2+}$ and Fe(2)$^{3+}$ for spin-up (Fig. 4). Majority spin 3d states of Fe(1)$^{3+}$ and minority spin states of Fe(2)$^{2+}$ cations are shifted below the O 2p states, which form the band in the energy range of \(-8 \) and \(-2 \) eV. In contrast to Fe$^{3+}$ states, the majority spin Fe(1)$^{2+}$ and minority spin Fe(2)$^{2+}$/3d states form the broad bands between \(-8 \) and \(-1 \) eV.

The obtained magnetic structure is almost antiferromagnetic (without spin moment per unit cell) with nearly the same spin moment per Fe atom with the same spin moment per Fe(1)$^{2+}$ and Fe(2)$^{2+}$ as well as per Fe(1)$^{3+}$ and Fe(2)$^{3+}$ cations. Using the moment populations in Table I, the calculated net moment is \(\sim-0.04 \mu_B\) per Fe atom, in exact agreement with the experimental value (Ref. 11).

The charge order obtained by LSDA+\( U \) in \(2a \times b \times c \) \( P2_1/c \) supercell is consistent with observed enlargement of

FIG. 3. The total DOS obtained from LSDA+\( U \) calculations with \(U=5.5\) eV and \(J=1\) eV for the low-temperature \( P2_1/c \) phase of Fe$_2$OBO$_3$. The top of the valence band is shown by dotted lines.
Thus, assuming a simple ionic model with the Coulomb interaction between Fe ions only the obtained CO pattern contradicts to the requirement of the minimal electrostatic energy. Indeed, the comparison of the Madelung energies shows that the energy lowers (about 0.07 eV per unit cell) if the nearest Fe(1) sites are occupied by Fe(1)$^{2+}$ and Fe(1)$^{3+}$ ions. This observation suggests that electron-lattice coupling rather than electrostatic repulsions drives the charge ordering in Fe$_2$OBO$_3$; the same conclusion was found for the charge order in Fe$_3$O$_4$.8–10

Although the corresponding total 3$d$ charges difference (0.34e) and disproportion of the total electron charges inside the atomic spheres of Fe$^{2+}$ and Fe$^{3+}$ cations (0.24e) is small, an analysis of occupation matrices of 3$d$ Fe(1)/Fe(2) minority/majority spin states confirms substantial charge separation. Thus, as shown in Table I, one of the $t_{2g}$ states of Fe(1)$^{2+}$ and Fe(2)$^{3+}$ cations is almost completely filled with the occupation numbers $n=0.9$, whereas the remained two $t_{2g}$ orbitals of the Fe$^{2+}$ cations have significantly smaller population of about 0.1. According to Ref. 10 we define an order parameter as the largest difference between Fe$^{2+}$ and Fe$^{3+}$ $t_{2g}$ populations. While due to strong static “screening” effects the order parameter introduced as the total 3$d$ charge difference between 2+ and 3+ Fe cations is ill defined, the well-defined order parameter is the difference of $t_{2g}$ occupancies for Fe$^{3+}$ and Fe$^{2+}$ cations, which amounts to 80% of ideal ionic CO model and clearly pronounces the existence of CO below the transition. The occupation matrices analysis shows that the change of the $t_{2g}$ occupations caused by the charge ordering is very effectively screened by the rearrangement of the other Fe electrons. Thus, significant contribution to the charge screening is provided by Fe $e_g$ states due to relatively strong $\sigma$ bonds with 2$p$ O states and, as a result, appreciable contribution to the occupied part of the valence band.

The occupied $t_{2g}$ states of Fe$^{2+}$ cations are predominantly of $d_{xy}$ character in the local cubic frame (according to that we consider the $\beta$ angle below the transition and coincides with charge ordering scheme proposed earlier by Attfield et al. in Ref. 11. It is described by the sloping 2+ and 3+ Fe cation lines alternately stacked along the $a$ direction, and could be considered as a quasi-one-dimensional analog of the Verwey CO model in the pyrochlore lattice of Fe$_3$O$_4$. Using the same $U$ and $J$ values we perform additional self-consistent LSDA + $U$ calculations for $P2_1/c$ unit cell as well as for double and triple along $a$-direction $P2_1/c$ supercells. But only self-consistent solutions with larger value of the total energy or with substantial magnetic moment per unit cell, which contradicts to the experimental data, were found. Also we found that other charge arrangements in $2a \times b \times c$ $P2_1/c$ supercell are unstable, and the stable one coincides with the CO found previously. Thus, the CO obtained for certain value of $U$ and $J$ does not depend on the initial charge arrangement. It is not possible to check all possible CO arrangements including more complex CO scenarios, but our results consistently indicate that the obtained CO solution is more favorable than other simple alternatives, and is the ground state of Fe$_2$OBO$_3$ in the low-temperature phase.

Because of the small monoclinic distortion of the low temperature $P2_1/c$ structure the distances between the nearest Fe(1) cations become slightly different. It is important to note that in the calculated CO pattern the shortest (2.957 Å) is the distance between the pairs of equally charged Fe(1) cations whereas the distance between Fe(1)$^{2+}$ and Fe(1)$^{3+}$ cations turns out to be larger (2.961 Å). On the contrary, the pairs of Fe(1) and Fe(2) sites with the shortest distance between them are occupied by the cations of different valency.
FIG. 6. The angular distribution of the majority and minority spin 3d electron density of the Fe(2) and Fe(1) cations, respectively, from different Fe ribbons (see Ref. 21). The size of orbital corresponds to its occupancy. The frame of four Fe(1) atoms from the Fe ribbon presented in Fig. 5 is shown by dashed lines.

later mark the orbital as $d_{xy}$ orbital). This is illustrated in Fig. 5, which shows the angular distribution of the majority and minority spin 3d electron density of the Fe(2) and Fe(1) cations, respectively.21 Thus, occupied Fe$^{2+}$ and unoccupied Fe$^{3+}$ cations are ordered alternately within the chain which is infinite along the $a$ direction. The angular distribution of charge density of the Fe(1) and Fe(2) cations, which correspondingly belongs to different Fe ribbons being formed a cross in the Fe$_2$OBO$_3$ structure projected on (100) plane (see Fig. 1) is shown in Fig. 6. An analysis of interatomic distances (Table II) shows that the average Fe(2)-O distance (2.109 Å) in the plane perpendicular to one of the diagonals of the distorted Fe(2)O$_6$ octahedron is considerably larger than average distances in the other two planes (2.055 and 2.083 Å). It turns out that the occupied Fe(2) $t_{2g}$ majority spin orbital is the one oriented in the plane with the largest average Fe(2)-O distance. The same is also true for the Fe(1) ion but in this case the variation of the average Fe(1)-O distances is smaller (2.111 vs 2.069 and 2.076 Å) and, as a consequence, the out-of-plane rotation of the occupied $t_{2g}$ minority spin orbital is stronger.

V. EXCHANGE COUPLING CONSTANTS

Using the LSDA+$U$ method the exchange interaction parameters have been calculated via the variation of ground state energy with respect to the magnetic-moment rotation angle. In Table III we have shown the total set of different intraribbon exchange parameters as well as a contribution of different subbands into exchange interactions. $J_i$ represents the effective pair exchange interaction between Fe atoms with effective Heisenberg Hamiltonian $H=\sum_{i>j}J_i\mathbf{e}_i\mathbf{e}_j$, where $e_i$ and $e_j$ are magnetic moment unit vectors at site $i$ and $j$. Positive (negative) values of $J$ correspond to the ferromagnetic (antiferromagnetic) coupling between Fe sites. The spatial representation of all these exchanges is schematically presented in Fig. 7. Surprisingly, only the exchange interaction parameter between Fe(2)$^{2+}$ and Fe(2)$^{3+}$ cations is ferromagnetic with relatively small value of $J_6=6$ K. In contrast, the nearest sites in quasi-one-dimensional Fe(1) chain are coupled antiferromagnetically with noticeably larger exchange absolute value of $|J_3|=69$ K. Furthermore, the exchange parameters between the nearest sites of two Fe(1) chains are relatively strong and antiferromagnetic (see $J_2$, $J_5$, and $J_6$ in Table III). Therefore, the Fe(1) sublattice is highly frustrated, while the relatively weak frustrations in the Fe(2) sublattice considerably reduce ferromagnetic interaction within Fe(2) chain. Also it is interesting to note that relat-

The occupied Fe$^{2+}$ and Fe$^{3+}$ cations are ordered alternately within infinite along $a$-axis chains of Fe atoms. This result is remarkable in view of the absence of directly observed CO atomic displacements in the experimental coordinates, and demonstrates the utility of the LSDA$+U$ method as an aide to experimental studies of CO structures. However, the charge order obtained by LSDA$+U$ is consistent with observed enlargement of the $\beta$ angle and coincides with charge ordering scheme proposed earlier by Attfield et al.\(^{11}\) It seems certain that Fe$_2$OBO$_3$ is charge ordered below $T_{co}$, and the absence of the long range charge ordering from x-ray, neutron, or electron diffraction arises from formation of charge order within small domains, which have been termed “Wigner nanocrystals”.\(^{22}\) Thus, the superstructure peaks are too weak and broad to be observed against background in diffraction patterns, whereas the observed long range monoclinic lattice distortion can arise despite a large concentration of defects as these preserve the direction of the monoclinic distortion, but do not propagate the coherent doubling of the lattice periodicity. An analysis of the exchange interaction parameters obtained by LSDA$+U$ method inevitably results in predominance of the interribbon exchange interactions which determine the whole $L$-type ferrimagnetic spin structure below $T_{co}$, in contrast to the ferromagnetic intrachain order due to $d^5-d^6$ superexchange.\(^{11,12}\)

VI. SUMMARY AND CONCLUSIONS

In summary, in the present LSDA$+U$ study of the low-temperature $P2_1/c$ phase of Fe$_2$OBO$_3$ we found a charge ordered insulator with an energy gap of 0.39 eV. While the screening of the charge disproportion is so effective that the total 3$d$ charge separation is rather small (0.34), the charge order is well pronounced with an order parameter defined as a difference of $t_{2g}$ occupancies of 2$^+$ and 3$^+$ Fe cations (0.8). The occupied Fe$^{2+}$ and Fe$^{3+}$ cations are ordered alternately within infinite along $a$-axis chains of Fe atoms. This result is remarkable in view of the absence of directly observed CO atomic displacements in the experimental coordinates, and demonstrates the utility of the LSDA$+U$ method as an aide to experimental studies of CO structures. However, the charge order obtained by LSDA$+U$ is consistent with observed enlargement of the $\beta$ angle and coincides with charge ordering scheme proposed earlier by Attfield et al.\(^{11}\) It seems certain that Fe$_2$OBO$_3$ is charge ordered below $T_{co}$, and the absence of the long range charge ordering from x-ray, neutron, or electron diffraction arises from formation of charge order within small domains, which have been termed “Wigner nanocrystals”.\(^{22}\) Thus, the superstructure peaks are too weak and broad to be observed against background in diffraction patterns, whereas the observed long range monoclinic lattice distortion can arise despite a large concentration of defects as these preserve the direction of the monoclinic distortion, but do not propagate the coherent doubling of the lattice periodicity. An analysis of the exchange interaction parameters obtained by LSDA$+U$ method inevitably results in predominance of the interribbon exchange interactions which determine the whole $L$-type ferrimagnetic spin structure below $T_{co}$, in contrast to the ferromagnetic intrachain order due to $d^5-d^6$ superexchange proposed earlier in Ref. 11.

2 Several reviews of research on the Verwey transition up to 1980 are contained in the special issue of Philos. Mag. B 42 (1980).

Here and in the following we assume a redistribution of charge between Fe\(t^2_g\) and other states using term screening.

The distribution is calculated according to \( \rho(\theta, \phi) = \sum_{m,m'} n_{m,m'} Y_m^*(\theta, \phi) Y_{m'}(\theta, \phi) \), where \( n_{m,m'} \) is the occupation matrix of 3d minority states of Fe(1) and 3d majority states of Fe(2) cations. The occupation matrices were calculated by the LSDA+\(U\) with \( U=5.5\) eV, \( J=1\) eV for the low-temperature \( P2_1/\overline{1}c \) phase of Fe\(_2\)OBO\(_3\). \( Y_m^*(\theta, \phi) \) are corresponding spherical harmonics.
